Function and Principle of Optical Splitters

Overview

Wave splitting involves dividing a light beam into multiple streams. The daughter streams can be equal or in some other ratio. The FBT splitter uses two (or more) fibers. The fibers' coating layer is removed. Both fibers, at the same time, are stretched under a heating zone thus forming a double cone. This special waveguide structure allows control of the splitting ratio via controlling length of the fiber torsion angle and stretch.

Key Takeaways

Optical splitters are passive devices that divide a single optical signal into multiple outputs or combine multiple signals into one, enabling efficient signal distribution in fiber optic networks.

Working Principle

Optical splitters operate based on optical coupling and waveguide interference, without requiring electrical power. When a light signal enters the splitter, it is redistributed across multiple output fibers according to the splitter's design and splitting ratio. The main mechanisms include: Signal Input: The incoming optical signal enters the splitter through a single input fiber.

Optical Coupling and Redistribution: Inside the splitter, the signal interacts with waveguides or fused fibers, which divide the light into multiple outputs. This can be achieved through parallel beam splitting (producing parallel output beams) or beam divergence splitting (producing diverging beams),. Signal Output: The divided signals exit through multiple output fibers, maintaining sufficient power for downstream devices.

Two primary types of splitters are used: FBT (Fused Biconical Taper) Splitters: Made by fusing and stretching fibers to form a waveguide structure. They are cost-effective and suitable for small-scale applications but may have limitations in uniformity and scalability.

PL

C (Planar Lightwave Circuit) Splitters: Manufactured using semiconductor processes like photolithography, integrating multiple waveguides on a chip. They provide high stability, low loss, and are ideal for large-scale deployments. Key performance parameters include splitting ratio, insertion loss, uniformity, and isolation, which determine how evenly the signal is distributed and how much power is lost during splitting.

Applications

Optical splitters are widely used in fiber optic communication systems, particularly in Passive Optical Networks (PONs) and Fiber to the Home (FTTH) deployments. Common applications include: Telecommunications: Sharing a single optical fiber among multiple users, reducing infrastructure costs.

FTT

H Networks: Distributing signals from an Optical Line Terminal (OLT) to multiple Optical Network Units (ONUs) at user premises, using centralized or cascaded splitting configurations. Data Centers: Efficiently managing optical signals for high-capacity networks. Bidirectional Communication: Supporting two-way data transmission, such as video calls or internet services, without additional power.

Splitters can be configured with various splitting ratios (e.g., 1: 2, 1: 32, 1: 64) depending on network requirements, and multiple stages of splitting can be cascaded to optimize signal distribution while minimizing loss. In summary, optical splitters are passive, reliable, and versatile components that enable efficient signal distribution in modern optical networks, supporting both small-scale and large-scale deployments.
